## Abstract

This paper presents a novel approach for learning classical planning action models from minimal input knowledge and using exclusively existing classical planners. First, the paper defines a classical planning compilation to learn action models from just pairs of initial and final states. Second, the paper explains how to collect informative examples using a classical planner based on pure exploratory search.

## Introduction

Off-the-shelf planners reason about action models that correctly and completely capture the possible world transitions (Geffner and Bonet 2013). Unfortunately building such models is complex even for planning experts limiting the potential of automated planning (Kambhampati 2007).

In Machine Learning (ML) models are not hand-coded but computed from examples (Michalski, Carbonell, and Mitchell 2013). Applying off-the-shelf ML to learning planning action models is not straightforward though. On the one hand ML examples use to represent objects features, encoded assigning values to a finite set of variables, while planning tasks include actions and are closer to the representation of procedures and behaviours. On the other hand, the traditional output of off-the-shelf ML techniques is a scalar value (an integer, in the case of classification tasks, or a real value, in the case of regression tasks) while classical planning actions are traditionally defined using declarative generative models. Finally the collection of *informative* examples for learning planning action models is complex. Planning actions include preconditions that are only satisfied by specific sequences of actions and often with a low probability of being chosen by chance (Fern, Yoon, and Givan 2004).

This work focuses on learning action models for classical planners. This is a well-studied problem where the dynamics of a given action can be captured lifting the literals that change between the pre and post-state of an action execution. There are sophisticated algorithms for this task, like ARMS (Yang, Wu, and Jiang 2007) or LOCM (Cresswell, McCluskey, and West 2013) that do not require the full knowledge of the states traversed by example plans. This

work aims going one step beyond these approaches and address learning classical planning action models when the only available knowledge is pairs of initial and final states.

Motivated by recent advances on effective exploration of planning state spaces () and on the learning of complex structures with classical planners (Segovia-Aguas, Jiménez, and Jonsson 2017), this paper introduces an innovative approach for learning classical planning action models. The contribution of this work are then two-fold:

1. An inductive learning algorithm that minimizes the required input knowledge, that is also flexible to different levels of input knowledge, and that can be defined as a classical planning compilation.
2. A method for autonomously collect *informative* examples for action model learning using an exploration-based classical planner.

## Background

Here we define the planning models we use on this work.

### Classical Planning

We use  $F$  to denote the set of *fluents* (propositional variables) describing a state. A *literal*  $l$  is a valuation of a fluent  $f \in F$ , i.e.  $l = f$  or  $l = \neg f$ . A set of literals  $L$  represents a partial assignment of values to fluents (WLOG we assume that  $L$  does not assign conflicting values to any fluent). We use  $\mathcal{L}(F)$  to denote the set of all literal sets on  $F$ , i.e. all partial assignments of values to fluents. A *state*  $s$  is a total assignment of values to fluents, i.e.  $|s| = |F|$ , so the number of states is  $2^{|F|}$ .

Under this formalism, a *classical planning frame* is a tuple  $\Phi = \langle F, A \rangle$ , where  $F$  is a set of fluents and  $A$  is a set of actions. Each action  $a \in A$  has a set of literals  $\text{pre}(a) \in \mathcal{L}(F)$  called the *precondition*, a set of positive effects  $\text{add}(a) \in \mathcal{L}(F)$  and a set of del effects  $\text{del}(a) \in \mathcal{L}(F)$ . An action  $a \in A$  is applicable in state  $s$  iff  $\text{pre}(a) \subseteq s$ , and the result of applying  $a$  in  $s$  is a new state  $\theta(s, a) = (s \setminus \neg \text{del}(a)) \cup \text{add}(a)$ .

Given a planning frame  $\Phi = \langle F, A \rangle$ , a *classical planning problem* is a tuple  $P = \langle F, A, I, G \rangle$ , where  $I$  is an initial state and  $G$  is a goal condition, i.e. a set of literals on  $F$ . A *plan* for  $P$  is an action sequence  $\pi = \langle a_1, \dots, a_n \rangle$  that induces a state sequence  $\langle s_0, s_1, \dots, s_n \rangle$  such that  $s_0 = I$

and, for each  $i$  such that  $1 \leq i \leq n$ ,  $a_i$  is applicable in  $s_{i-1}$  and generates the successor state  $s_i = \theta(s_{i-1}, a_i)$ . The plan  $\pi$  solves  $P$  if and only if  $G \subseteq s_n$ , i.e. if the goal condition is satisfied following the application of  $\pi$  in  $I$ .

We assume that fluents are instantiated from predicates, as in PDDL (Fox and Long 2003). Specifically, there exists a set of predicates  $\Psi$ , and each predicate  $p \in \Psi$  has an argument list of arity  $ar(p)$ . Given a set of objects  $\Omega$ , the set of fluents  $F$  is then induced by assigning objects in  $\Omega$  to the arguments of predicates in  $\Psi$ , i.e.  $F = \{p(\omega) : p \in \Psi, \omega \in \Omega^{ar(p)}\}$  where, given a set  $X$ ,  $X^n$  is the  $n$ -th Cartesian power of  $X$ .

Likewise we assume actions in  $A$  are instantiated from operator schema as follows. Let us define  $\Omega_v = \{var_1, \dots, var_v\}$  as a new set of objects,  $\Omega_v \cap \Omega = \emptyset$ , representing variable names. The number of *variable* objects,  $|\Omega_v|$ , is given by the action with the maximum arity. For instance, in the blockworld  $\Omega_v = \{var_1, var_2\}$  since action *stack*, Figure 1, (and *unstack*) has two parameters. Let us define a new set of fluents,  $F_v \cap F = \emptyset$ , that result instantiating  $\Psi$  but using only the variable objects in  $\Omega_v$ .

```
(:action stack
:parameters (?x1 ?x2)
:precondition (and (holding ?x1)
                  (clear ?x2))
:effect (and (not (holding ?x1))
             (not (clear ?x2))
             (clear ?x1)
             (handempty)
             (on ?x1 ?x2)))
```

Figure 1: Example of the *stack* planning action schema from the blockworld as represented in PDDL.

Now we are ready to define an operator schema  $\xi \in \Xi$ :

- The *header*: a fluent  $header(name(\xi), pars(\xi))$  built using the action name,  $name(\xi) \in \{stack, unstack, pickup, putdown\}$  for the blockworld, and a list of variables,  $pars(\xi) \in \Omega_v^{ar(\xi)}$ .
- The operator *body* comprises: the *preconditions*,  $pre(\xi) \subseteq F_v$ , the *positive effects*,  $add(\xi) \subseteq F_v$ , and the *negative effects*,  $del(\xi) \subseteq F_v$  such that,  $del(\xi) \subseteq pre(\xi)$ ,  $del(\xi) \cap add(\xi) = \emptyset$  and  $pre(\xi) \cap add(\xi) = \emptyset$ .

### Classical Planning with Conditional Effects

Conditional effects make it possible to repeatedly refer to the same action even though their precise effects depend on the current state. In this case each action  $a \in A$  has a set of literals  $pre(a) \in \mathcal{L}(F)$  called the *precondition* and a set of conditional effects  $cond(a)$ . Each conditional effect  $C \triangleright E \in cond(a)$  is composed of two sets of literals  $C \in \mathcal{L}(F)$  (the condition) and  $E \in \mathcal{L}(F)$  (the effect). An action  $a \in A$  is applicable in state  $s$  if and only if  $pre(a) \subseteq s$ , and the resulting set of *triggered effects* is

$$eff(s, a) = \bigcup_{C \triangleright E \in cond(a), C \subseteq s} E,$$

i.e. effects whose conditions hold in  $s$ . The result of applying  $a$  in  $s$  is a new state  $\theta(s, a) = (s \setminus \neg eff(s, a)) \cup eff(s, a)$ .

### Learning classical planning action models from minimal input knowledge

This section formalizes the different learning tasks we address in the paper according to the available amount of input knowledge.

#### Learning classical planning action models from plans

This task is defined as  $\Lambda = \langle \Psi, \Pi, \Sigma \rangle$ :

- $\Psi$  the set of predicates that define the abstract state space of a given planning domain. This set includes the predicates describing the actions header.
- $\Pi = \{\pi_1, \dots, \pi_t\}$  is the given set of example plans,
- $\Sigma = \{\sigma_1, \dots, \sigma_t\}$  is a set of labels s.t. each plan  $\pi_i$ ,  $1 \leq i \leq t$ , has an associated label  $\sigma_i = (s_i, s'_i)$  where  $s'_i$  is the state resulting from executing  $\pi_i$  starting from the state  $s_i$ .

A solution to the learning task  $\Lambda$  is a set of operator schema  $\Xi$  that is compliant with the predicates in  $\Psi$ , the example plans  $\Pi$ , and their labels  $\Sigma$ .

#### Learning classical planning action models from states

As explained in this paper we aim to reduce the amount of input knowledge provided to the learning task so we redefine it as  $\Lambda' = \langle \Psi, \Sigma \rangle$ . A solution to the  $\Lambda'$  learning task is a set of operator schema  $\Xi$  that is compliant with the predicates in  $\Psi$ , and the given set of initial and final states.

### Learning action models from states using a classical planner

Our approach for addressing  $\Lambda' = \langle \Psi, \Sigma \rangle$  is compiling this learning task into a classical planning task that can later be solved by an off-the-shelf classical planner. The intuition behind the compilation is that a solution to  $P_\Lambda$  is a sequence of actions that first, programs the action action model (i.e. the  $pre(\xi)$ ,  $del(\xi)$  and  $add(\xi)$  for each  $\xi \in \Xi$ ) and then, sequentially, validates the programmed action model in the labels  $\Sigma$  one after the other.

To formalize the compilation we first define  $t$  classical planning instances  $P_1 = \langle F, A, I_1, G_1 \rangle, \dots, P_t = \langle F, A, I_t, G_t \rangle$ , that belong to the same planning frame  $\Phi = \langle F, A \rangle$  (i.e. share the same fluents and actions and differ only in the initial state and goals). Let  $\Omega$  be the set of objects that appear in the states  $\Sigma$ , i.e.,  $\Omega = \{o | o \in s_i \cup s'_i, 1 \leq i \leq t\}$ . Then  $F$  is the set of fluents built instantiating the predicates in  $\Psi$  with the objects in  $\Omega$  and  $A = \emptyset$ . Finally the initial state  $I_i$ ,  $1 \leq i \leq t$ , is given by the state  $s_i \in \sigma_i$  and the goals are defined by the state  $s'_i \in \sigma_i$ .

Now we are ready to define the compilation for learning action models using a classical planner. Given a learning task  $\Lambda' = \langle \Psi, \Sigma \rangle$  the compilation outputs a classical planning task  $P_\Lambda = \langle F_\Lambda, A_\Lambda, I_\Lambda, G_\Lambda \rangle$  where:

- $F_\Lambda$  extends  $F$  with:

- Fluents representing the programmed action model:  $header(\xi)$ ,  $pre_f(\xi)$ ,  $del_f(\xi)$  and  $add_f(\xi)$  where  $f \in F_v$  and  $\xi \in \Xi$ .
- Fluents  $\{test_i\}_{1 \leq i \leq t}$ , indicating the example where the programmed model is currently being validated.
- $I_\Lambda$ , contains the fluents from  $F$  that encode the initial state  $s_1 \in P_1$  and the header of the actions.
- $G_\Lambda = \{test_i\}_{1 \leq i \leq t}$ , indicates that the programmed model is validated in all the examples.
- $A_\Lambda$  replaces the actions in  $A$  with actions of three types:
  1. The actions for programming an action schema:
    - A *precondition*  $f \in F_v$  in the action schema  $\xi \in \Xi$ :
 
$$pre(programPre_{\xi,f}) = \{\neg pre_f(\xi), \neg del_f(\xi), \neg add_f(\xi)\}.$$

$$cond(programPre_{\xi,f}) = \{\emptyset\} \triangleright \{pre_f(\xi)\}.$$
    - A *negative effect*  $f \in F_v$  in the action schema  $\xi \in \Xi$ :
 
$$pre(programDel_{\xi,f}) = \{pre_f(\xi), \neg del_f(\xi), \neg add_f(\xi)\}.$$

$$cond(programDel_{\xi,f}) = \{\emptyset\} \triangleright \{del_f(\xi)\}.$$
    - A *positive effect*  $f \in F_v$  in the action schema  $\xi \in \Xi$ :
 
$$pre(programAdd_{\xi,f}) = \{\neg pre_f(\xi), \neg del_f(\xi), \neg add_f(\xi)\}.$$

$$cond(programAdd_{\xi,f}) = \{\emptyset\} \triangleright \{add_f(\xi)\}.$$
  2. The actions for applying an already programmed operator schema  $\xi \in \Xi$  and that is bound with objects  $v' \in \Omega^{ar(\xi)}$ 

$$pre(apply_{\xi,v,v'}) = \{header(\xi)\} \cup \{pre_f(\xi) \implies p(v')\}_{\forall p \in \Psi}.$$

$$cond(apply_{\xi,v,v'}) = \{del_f(\xi)\} \triangleright \{\neg p(v')\}_{\forall p \in \Psi},$$

$$\{add_f(\xi)\} \triangleright \{p(v')\}_{\forall p \in \Psi}.$$
  3. The actions for changing the active example where the model is currently being validated.
 
$$pre(validate_i) = G_i \cup \{\{test_j\}_{j=1 \leq j < i}\}.$$

$$cond(validate_i) = \{\emptyset\} \triangleright \{test_i\}.$$

**Lemma 1.** Any classical plan  $\pi$  that solves  $P_\Lambda$  induces a valid action model that solves the learning task  $\Lambda$ .

*Proof sketch.* Once an action schema is programmed it can only be executed. The only way of achieving a test fluent is by achieving the goal state in its associated label. If this is done for all the input examples it means that the programmed model is compliant with the learning input knowledge and hence, solves the action model learning task.  $\square$

## Learning action models from plans using a classical planner

Interestingly the compilation is also valid for partially specified action models since the known preconditions and effects can be part of the initial state  $I_\Lambda$ . With this regard the approach allows also transfer learning in which we generate the action model for a given sub-task and then encode this model as already programmed actions for learning new or more challenging action models.

Evenmore, the compilation is extensible to the scenario in which a set of action plans  $\Pi$  is available s.t., each plan  $\pi_i \in \Pi$ ,  $1 \leq i \leq t$ , is a solution to the corresponding classical planning instance  $P_i = \langle F, A, I_i, G_i \rangle$ . In this case:

- $F_\Lambda$  have to include the set of fluents  $F_{plan} = \{plan(name(\xi), i, \Omega^{ar(a)})\}$  for encoding the plans in  $\Pi$ . Fluents  $at_i$  and  $next_{i,i_2}$ ,  $1 \leq i < i_2 \leq n$ , indicate the plan step where the programmed model is being validated and  $n$  is the max length of a plan in  $\Pi$ .
- $I_\Lambda$  is extended with the fluents from  $F_{plan}$  that encode the plan  $\pi_1 \in \Pi$  for solving  $P_1$ , and the fluents  $at_1$  and  $\{next_{i,i_2}\}$ ,  $1 \leq i < i_2 \leq n$ , for indicating that the plan step where to start validating the programmed model. The goals are like in the original compilation.
- With respect to the actions,
  1. The actions for programming an action schema are the same.
  2. The actions for applying an operator schema have an extra precondition  $f \in F_{plan}$  s.t.  $f$  encodes the current plan step and the extra conditional effect  $\{at_i\} \triangleright \{\neg at_i, at_{i+1}\}_{\forall i=1 \leq i < n}$  for advancing to the next plan step.
  3. The actions for changing the active test have an extra precondition,  $at_{|\Pi_i|}$ , to indicate that we simulated the full current plan and extra conditional states to load the next plan where to validate the model,
 
$$\{\emptyset\} \triangleright \{\neg at_{|\Pi_i|}, at_1\},$$

$$\{\emptyset\} \triangleright \{\neg plan(\xi, k, v)\}_{1 \leq k < |\Pi_i|},$$

$$\{\emptyset\} \triangleright \{plan(\xi, k, v)\}_{1 \leq k < |\Pi_{i+1}|}.$$

## Generating informative learning examples

Observation: If a predicate is not appearing either in the initial not in the final state it will not appear in the action model.

## Evaluation

Because we are evaluating our learned models empirically, evaluation is closely related to the generation of informative and diverse learning examples.

Mirar evaluacion basada en los domain transition graphs.

## Related work

## Conclusions

Learning action models from examples allows the reformulation of a domain theory.
